## Abstract

An Eulerian model for the dispersion of a passive tracer over a simplified slope driven by a thermally driven circulation is presented here. The source of the tracer is point-like and the emission continuous, the local circulation is a pure anabatic flow modeled following Prandtl's (1942) steady state model. The eddy diffusivity is considered, at first, constant along the vertical direction, and later specific parameterizations are tested. The incapability of a classical gaussian model to forecast the concentration field is shown through a comparison between the results of the Gaussian and Eulerian models. A study of the sensitivity of the concentration field to the position of the source and to the maximum values of the wind field is proposed. Moreover, a mathematical relationship between the position and the intensity of the ground concentration field, together with its dependence to the environmental parameters is found.
